References

Reservoir sampling is a family of randomized algorithms for choosing a simple random sample, without replacement, of k items from a population of unknown size n in a single pass over the items. The size of the population n is not known to the algorithm and is typically too large for all n items to fit into

main memory. The population is revealed to the algorithm over time, and the algorithm cannot look back at previous items. At any point, the current state of the algorithm must permit extraction of a simple random sample without replacement of size k over the part of the population seen so far. Motivation [edit]

sequence. If we know the total number of items n and can access the items arbitrarily, then the solution is easy: select 10 distinct indices i between 1 and n with equal probability, and keep the i-th elements. The problem is that we do not always know the exact n in advance.

Suppose we see a sequence of items, one at a time. We want to keep ten items in memory, and we want them to be selected at random from the

Simple: Algorithm R [edit]

A simple and popular but slow algorithm, Algorithm R, was created by Jeffrey Vitter.[1] Initialize an array R indexed from 1 to k, containing the first k items of the input x_1, \ldots, x_k . This is the *reservoir*.

For each new input x_i , generate a random number j uniformly in $\{1,\ldots,i\}$. If $j\in\{1,\ldots,k\}$, then set $R[j]:=x_i$, otherwise, discard x_i . Return R after all inputs are processed. This algorithm works by induction on $i \geq k$. **Proof**

When i=k, Algorithm R returns all inputs, thus providing the basis for a proof by mathematical induction. Here, the induction hypothesis is that the probability that a particular input is included in the reservoir just before the (i+1)-th input is processed is $\frac{k}{i}$ and we must show that the probability that a particular input is included in the reservoir is $\frac{k}{i+1}$ just after the (i+1)-th input is processed. Apply Algorithm R to the (i+1)-th input. Input x_{i+1} is included with probability $\frac{\kappa}{i+1}$ by definition of the algorithm. For any other $j \in \{k+1,\ldots,i+1\}$, by the induction hypothesis, the probability that the input $x_r \in \{x_1,\ldots,x_i\}$ is included in the reservoir just before the (i+1)-th input is processed is $\frac{k}{i}$. The probability that it is still included in the reservoir after x_{i+1} is processed (in other

words, that x_r is not replaced by x_{i+1}) is $rac{k}{i} imes \left(1-rac{1}{i+1}
ight)=rac{k}{i+1}$. The latter result follows from the assumption that the integer j is generated uniformly at random; once it becomes clear that a replacement will in fact occur, the probability that x_r in particular is replaced by x_{i+1} is $\frac{k}{i+1}\frac{1}{k}=\frac{1}{i+1}$. We have shown that the probability that a new input enters the reservoir is equal to the probability that an existing input in the reservoir is retained. Therefore, we conclude by the principle of mathematical induction that Algorithm R does indeed produce a random sample of the inputs. While conceptually simple and easy to understand, this algorithm needs to generate a random number for each item of the input, including the items that

to be unnecessarily slow if the input population is large. This is *Algorithm R*, implemented as follows: (* S has items to sample, R will contain the result *)

are discarded. The algorithm's asymptotic running time is thus O(n). Generating this amount of randomness and the linear run time causes the algorithm

```
ReservoirSample(S[1..n], R[1..k])
   // fill the reservoir array
   for i := 1 to k
       R[i] := S[i]
   // replace elements with gradually decreasing probability
   for i := k+1 to n
     (* randomInteger(a, b) generates a uniform integer from the inclusive range {a, ..., b} *)
     j := randomInteger(1, i)
     if j <= k
         R[j] := S[i]
Optimal: Algorithm L [edit]
```

 $\{1,\ldots,n\}$.

Reservoir sampling

From Wikipedia, the free encyclopedia

Article Talk

If we generate n random numbers $u_1,\ldots,u_n\sim U[0,1]$ independently, then the indices of the smallest k of them is a uniform sample of the k-subsets of The process can be done without knowing n:

Keep the smallest k of u_1,\ldots,u_i that has been seen so far, as well as w_i , the index of the largest among them. For each new u_{i+1} , compare it with u_{w_i} . If $u_{i+1} < u_{w_i}$, then discard u_{w_i} , store u_{i+1} , and set w_{i+1} to be the index of the largest among them. Otherwise, discard u_{i+1} , and

set $w_{i+1}=w_i$. Now couple this with the stream of inputs x_1, \ldots, x_n . Every time some u_i is accepted, store the corresponding x_i . Every time some u_i is discarded, discard the corresponding x_i .

This algorithm still needs O(n) random numbers, thus taking O(n) time. But it can be simplified. First simplification: it is unnecessary to test new u_{i+1}, u_{i+2}, \ldots one by one, since the probability that the next acceptance happens at u_{i+l} is

 $(1-u_{w_i})^{l-1}-(1-u_{w_i})^l$, that is, the interval l of acceptance follows a geometric distribution. Second simplification: it's unnecessary to remember the entire array of the smallest k of u_1, \ldots, u_i that has been seen so far, but merely w, the largest

(* S has items to sample, R will contain the result *)

among them. This is based on three observations: • Every time some new x_{i+1} is selected to be entered into storage, a uniformly random entry in storage is discarded. $ullet \ u_{i+1} \sim U[0,w]$

ullet w_{i+1} has the same distribution as $\max\{u_1,\ldots,u_k\}$, where all $u_1,\ldots,u_k\sim U[0,w]$ independently. This can be sampled by first sampling $u \sim U[0,1]$, then taking $w \cdot u^{rac{\pi}{k}}$.

This is Algorithm L, [2] which is implemented as follows:

ReservoirSample(S[1..n], R[1..k]) // fill the reservoir array for i = 1 to k R[i] := S[i](* random() generates a uniform (0,1) random number *) W := exp(log(random())/k)while i <= n i := i + floor(log(random())/log(1-W)) + 1**if** i <= n (* replace a random item of the reservoir with item i *) R[randomInteger(1,k)] := S[i] // random index between 1 and k, inclusiveW := W * exp(log(random())/k)This algorithm computes three random numbers for each item that becomes part of the reservoir, and does not spend any time on items that do not. Its

random deviates from exotic or hard-to-compute distributions. With random sort [edit] If we associate with each item of the input a uniformly generated random number, the k items with the largest (or, equivalently, smallest) associated values

form a simple random sample. [3] A simple reservoir-sampling thus maintains the k items with the currently largest associated values in a priority queue.

expected running time is thus $O(k(1 + \log(n/k)))$, [2] which is optimal. [1] At the same time, it is simple to implement efficiently and does not depend on

S is a stream of items to sample S.Current returns current item in stream

```
S.Next advances stream to next position
   min-priority-queue supports:
     Count -> number of items in priority queue
     Minimum -> returns minimum key value of all items
      Extract-Min() -> Remove the item with minimum key
      Insert(key, Item) -> Adds item with specified key
  ReservoirSample(S[1..?])
   H := new min-priority-queue
   while S has data
      r := random() // uniformly random between 0 and 1, exclusive
     if H.Count < k</pre>
        H.Insert(r, S.Current)
      else
        // keep k items with largest associated keys
        if r > H.Minimum
          H.Extract-Min()
          H.Insert(r, S.Current)
     S.Next
    return items in H
The expected running time of this algorithm is O(n + k \log k \log(n/k)) and it is relevant mainly because it can easily be extended to items with weights.
Weighted random sampling [edit]
```

This method, also called sequential sampling, is incorrect in the sense that it does not allow to obtain a priori fixed inclusion probabilities. Some applications require items' sampling probabilities to be according to weights associated with each item. For example, it might be required to sample queries

in a search engine with weight as number of times they were performed so that the sample can be analyzed for overall impact on user experience. Let the

min-priority-queue supports:

Count -> number of items in the priority queue

S[i].Weight contains weight for each item

WeightedReservoir-Chao(S[1..n], R[1..k])

// fill the reservoir array

WSum := 0

after the replacement.

Algorithm A-Chao with Jumps [edit]

i)".

Minimum -> minimum key of any item in the priority queue

weight of item i be w_i , and the sum of all weights be W. There are two ways to interpret weights assigned to each item in the set: [4] 1. In each round, the probability of every *unselected* item to be selected in that round is proportional to its weight relative to the weights of all unselected items. If X is the current sample, then the probability of an item $i \notin X$ to be selected in the current round is $w_i/(W-\sum_{i\in X}w_i)$. 2. The probability of each item to be included in the random sample is not proportional to its relative weight, i.e., w_i/W . A simple counter-example is the case, e.g., k=n.

Algorithm A-Res [edit] The following algorithm was given by Efraimidis and Spirakis that uses interpretation 1:^[5]

S is a stream of items to sample S.Current returns current item in stream

S.Weight returns weight of current item in stream S.Next advances stream to next position The power operator is represented by ^ min-priority-queue supports:

Count -> number of items in priority queue

```
Minimum() -> returns minimum key value of all items
      Extract-Min() -> Remove the item with minimum key
      Insert(key, Item) -> Adds item with specified key
  ReservoirSample(S[1..?])
    H := new min-priority-queue
    while S has data
      r := random() ^ (1/S.Weight) // random() produces a uniformly random number in (0,1)
      if H.Count < k</pre>
         H.Insert(r, S.Current)
       else
        // keep k items with largest associated keys
         if r > H.Minimum
           H.Extract-Min()
           H.Insert(r, S.Current)
      S.Next
    return items in H
This algorithm is identical to the algorithm given in Reservoir Sampling with Random Sort except for the generation of the items' keys. The algorithm is
equivalent to assigning each item a key r^{1/w_i} where r is the random number and then selecting the k items with the largest keys. Equivalently, a more
numerically stable formulation of this algorithm computes the keys as -\ln(r)/w_i and select the k items with the smallest keys. [6][failed verification]
Algorithm A-ExpJ [edit]
The following algorithm is a more efficient version of A-Res, also given by Efraimidis and Spirakis:<sup>[5]</sup>
```

S is a stream of items to sample S.Current returns current item in stream S.Weight returns weight of current item in stream S.Next advances stream to next position The power operator is represented by ^

```
Extract-Min() -> Remove the item with minimum key
      Insert(Key, Item) -> Adds item with specified key
  ReservoirSampleWithJumps(S[1..?])
    H := new min-priority-queue
    while S has data and H.Count < k</pre>
      r := random() ^ (1/S.Weight) // random() produces a uniformly random number in (0,1)
      H.Insert(r, S.Current)
      S.Next
    X := log(random()) / log(H.Minimum) // this is the amount of weight that needs to be jumped over
    while S has data
      X := X - S_*Weight
      if X <= 0
        t := H.Minimum ^ S.Weight
        r := random(t, 1) \land (1/S.Weight) // random(x, y) produces a uniformly random number in (x, y)
        H.Extract-Min()
        H.Insert(r, S.Current)
        X := log(random()) / log(H.Minimum)
      S.Next
    return items in H
This algorithm follows the same mathematical properties that are used in A-Res, but instead of calculating the key for each item and checking whether that
item should be inserted or not, it calculates an exponential jump to the next item which will be inserted. This avoids having to create random variates for
each item, which may be expensive. The number of random variates required is reduced from O(n) to O(k \log(n/k)) in expectation, where k is the
reservoir size, and n is the number of items in the stream. [5]
Algorithm A-Chao [edit]
Following algorithm was given by M. T. Chao uses interpretation 2:[7]
    S has items to sample, R will contain the result
```

for i := 1 to k R[i] := S[i]WSum := WSum + S[i].Weight **for** i := k+1 **to** n WSum := WSum + S[i].Weight p := S[i].Weight / WSum // probability for this item j := random(); // uniformly random between 0 and 1 if j <= p // select item according to probability</pre>

For each item, its relative weight is calculated and used to randomly decide if the item will be added into the reservoir. If the item is selected, then one of

the existing items of the reservoir is uniformly selected and replaced with the new item. The trick here is that, if the probabilities of all items in the reservoir

are already proportional to their weights, then by selecting uniformly which item to replace, the probabilities of all items remain proportional to their weight

Note that Chao doesn't specify how to sample the first *k* elements. He simple assumes we have some other way of picking them in proportion to their

weight. Chao: "Assume that we have a sampling plan of fixed size with respect to S_k at time A; such that its first-order inclusion probability of X_t is $\pi(k)$

R[randomInteger(1,k)] := S[i] //uniform selection in reservoir for replacement

Similar to the other algorithms, it is possible to compute a random weight j and subtract items' probability mass values, skipping them while j > 0, reducing the number of random numbers that have to be generated. [4]

```
S has items to sample, R will contain the result
    S[i].Weight contains weight for each item
   *)
  WeightedReservoir-Chao(S[1..n], R[1..k])
    WSum := 0
   // fill the reservoir array
    for i := 1 to k
        R[i] := S[i]
        WSum := WSum + S[i].Weight
   j := random() // uniformly random between 0 and 1
    pNone := 1 // probability that no item has been selected so far (in this jump)
    for i := k+1 to n
      WSum := WSum + S[i].Weight
      p := S[i].Weight / WSum // probability for this item
      j -= p * pNone
      pNone := pNone *(1 - p)
      if j <= 0
          R[randomInteger(1,k)] := S[i] //uniform selection in reservoir for replacement
          j = random()
          pNone := 1
Relation to Fisher-Yates shuffle [edit]
Suppose one wanted to draw k random cards from a deck of cards. A natural approach would be to shuffle the deck and then take the top k cards. In the
general case, the shuffle also needs to work even if the number of cards in the deck is not known in advance, a condition which is satisfied by the inside-
```

out version of the Fisher–Yates shuffle:[8] (* S has the input, R will contain the output permutation *) Shuffle(S[1..n], R[1..n])

j := randomInteger(1, i) // inclusive range

R[1] := S[1]

for i from 2 to n do

R[i] := R[j]R[j] := S[i]Note that although the rest of the cards are shuffled, only the first k are important in the present context. Therefore, the array R need only track the cards in

the first k positions while performing the shuffle, reducing the amount of memory needed. Truncating R to length k, the algorithm is modified accordingly:

```
(* S has items to sample, R will contain the result *)
ReservoirSample(S[1..n], R[1..k])
 R[1] := S[1]
  for i from 2 to k do
     j := randomInteger(1, i) // inclusive range
     R[i] := R[j]
     R[i] := S[i]
  for i from k + 1 to n do
     j := randomInteger(1, i) // inclusive range
     if (j <= k)
         R[j] := S[i]
```

Since the order of the first k cards is immaterial, the first loop can be removed and R can be initialized to be the first k items of the input. This yields *Algorithm R.* Statistical properties [edit]

Probabilities of selection of the reservoir methods are discussed in Chao (1982)^[7] and Tillé (2006).^[9] While the first-order selection probabilities are equal

to k/n (or, in case of Chao's procedure, to an arbitrary set of unequal probabilities), the second order selection probabilities depend on the order in which

the records are sorted in the original reservoir. The problem is overcome by the cube sampling method of Deville and Tillé (2004). [10] Limitations [edit] Reservoir sampling makes the assumption that the desired sample fits into main memory, often implying that k is a constant independent of n. In

implementations for this problem have been proposed.[11] References [edit] 1. ^ a b Vitter, Jeffrey S. (1 March 1985). "Random sampling with a 5. ^ a b c Efraimidis, Pavlos S.; Spirakis, Paul G. (2006-03-16). "Weighted
